## Supplementary Figure S1. Classification of exons and coding segments.

Top: pseudocode definitions of elementary alternatives.
Bottom: a schematic representation of an example (a gene with three isoforms). Shading types for different types of coding segments are listed under the scheme. Vertical lines correspond to splicing sites. Five-component strings (ECIAD) representing types of elementary alternatives are shown above each exon, e.g., cassette exon having two variants with different donor sites is described as (-C-D), two adjacent exons included independently were both cassette and mutually exclusive (EC---), whereas a constitutive exon was described by the empty string (-----).

Consider two isoforms.
Consider an exon in one isoform.
if common segments with two or more exons from the other isoform then retained-intron exon (I)
if common segments with one exon from the other isoform then
if alternative region (in either isoform) 5' of the common region
then alternative-acceptor exon (A)
if alternative region (in either isoform) $3^{\prime}$ of the common region then alternative-donor exon (D)
if no common segments with the other isoform then
if common regions on both sides then consider the closest pair if no other complete exons between the common regions then cassette exon (C)
else (at least one exon in the other isoform completely between the common regions) then mutually exclusive, or alternative, exon (E)
if common regions only at 3'-side then consider the closest one if no other complete exons $5^{\prime}$ of the common region then cassette exon (C)
else (at least one exon in the other isoform completely 5' of the common region)
then mutually exclusive, or alternative, exon (E)
if common regions only at $5^{\prime}$-side then consider the closest one if no other complete exons $3^{\prime}$ of the common region then cassette exon (C) else (at least one exon in either isoform completely $3^{\prime}$ of the common region)
then mutually exclusive, or alternative, exon (E)

- exon $\quad$ - alternative coding segment $\quad$ - constitutive coding segment

## Supplementary Figure S2. Definition of conserved and missing exons.

Top: formal definitions as the pseudocode.
Bottom: schematic representations of cases when exons that contain both missing and conserved coding segments are considered missing. The isoform 1 exons differ from the isoform 2 exons by missing segments.

```
Consider an exon
if there is at least one missing coding segment in the exon then
    if the exon does not contain a conserved coding segment specific for
    this exon then
        if the exon is a retained-intron exon
            then the exon is considered missing *
        else
            if there exists a shorter exon containing the same set
            of conserved segments
                    then the exon is considered missing **
                else
                    if there exists a (not retained-intron) exon containing the
                    same set of conserved segments plus other conserved segments
                    then the exon is considered missing ***
                    else the exon is considered conserved
    else (the exon contains a coding segment specific for this exon)
            the exon is considered conserved
else (all coding segments are conserved)
    the exon is considered conserved
```

missing segment: similarity in alignments of all isoforms including this segment was less than 35\%
conserved segment: similarity in the alignment of at least one isoform including this segment was greater than $\mathbf{3 5 \%}$

## Supplementary Figure S3. Dependence of the slice similarity score on its length for D.melanogaster-D.pseudoobscura pairs.

Slices are defined as coding regions between two adjacent intron shadows (irrespective of the origin of these shadows in Dme or Dps). The $35 \%$ cutoff is shown by a straight line. Slices in different types of exons (see definitions in the text) are considered separately. Conserved exactly slices coincide with exons. Negative and low positive similarity scores arise from non-conserved slices whose alignment is constrained by the alignment of adjacent conserved regions.

Supplementary Figure S4. The dependence of the slice similarity score on its length for D.melanogaster-A.gambiae pairs.

For definitions see the legend to Fig. S3. Existence of a large number of sub-cutoff slices shows that the alignment at exon termini is not very reliable.

## Supplementary Figure S5. Classification of slice events for the D.melanogaster exons.

 Definition of slices see in the legend to Suppl. Fig. 3.$$
\begin{array}{ll}
\mathbf{d} \text { - divided exon; } & \mathbf{j} \text { - joined exon; } \\
\text { e - exactly conserved exon; } & \mathbf{m} \text { - mixed; }
\end{array}
$$

Supplementary Figure S6. Different types of events for the same exon dependent on an isoform.
$\mathbf{e}$ - exactly conserved exon; $\mathbf{d}$ - exon divided event; $\mathbf{j}$ - exon joined event.

## Supplementary Figure S7. Filtering of the dataset.

Supplementary Table S1. Types of elementary alternatives and conservation (valid alignment) of D. melonogaster exons in the D. pseudoobscura and A. gambiae genomes. Top-down: DmeDps, small (curated) sample; Dme-Dps, large (non-curated) sample; Dme-Aga, small (curated) sample; Dme-Aga, large (non-curated) sample.
